Abstract: The paper presents an automated method for the assessment and classification of puckering defects detected during the preproduction control stage of the sewing machine or product inspection. In this respect, we have presented the possible causes and remedies of the wrinkle nonconformities. Subjective factors related to the control environment and operators during the seams evaluation can be reduced using an automated system whose operation is based on image processing. Our implementation involves spectral image analysis using Fourier transform and an unsupervised neural network, the Kohonen Map, employed to classify material specimens, the input images, into five discrete degrees of quality, from grade 5 (best) to grade 1 (the worst). The puckering features presented in the learning and test images have been pre-classified using the seam puckering quality standard. The network training stage will consist in presenting five input vectors (derived from the down-sampled arrays), representing the puckering grades. The puckering classification consists in providing an input vector derived from the image supposed to be classified. A scalar product between the input values vectors and the weighted training images is computed. The result will be assigned to one of the five classes of which the input image belongs. Using the Kohonen network the puckering defects were correctly classified in proportion of 71.42%.

Key words: Seams, pucker, image processing, neural network, Discrete Fourier Transform.

1. QUALITY AND AUTOMATION IN THE TEXTILE INDUSTRY

The textile industry is one of the traditional and dynamic sectors where the customer quality requirements are constantly changing as a result of trends in fashion and the development of production tools. In order to satisfy clients demands, the variables that affect product quality must be kept under control during the production cycle: design, manufacturing, delivery and maintenance.

The evaluation process of a sewn product relating to appearance and performance have to rely on a holistic perspective that includes both fabrics and sewing threads assessment, but also consider their interactions during sewing, wearing and maintenance of the product. Throughout the manufacturing process, the woven, non-woven or knitted fabrics are controlled from two to more than six times in order to detect the defects which may occur, followed by their classification and if possible, remedying. A good compatibility between sewing thread and materials will influence the product quality and productivity. Otherwise, during the sewing process, the fabric is damaged or the machine stops at unanticipated time intervals [1].

After execution, a correct seam need to be smooth and flat, without puckering, tuck developing or seam damage, having an appropriate behavior during pressing and cleaning. There are several standard test methods for evaluating the interactions between the threads and fabrics after the
execution of the seams and stitching. ASTM D1683 assess seam strength, slippage, failure, damage, pucker and jamming before and after cleaning. ISO 7770, AATCC 88 B and AATCC 143 standards use sets of images and rating scales in order to evaluate the appearance of seams, using grades from 1 (worse) to 5 (best quality seam). Inspectors should compare the stitching samples with the standard images, in different environments, which cause subjective results.

Due to long reaction time and fatigue of the human operator, an automatic inspection would be able to verify and classify the seams with a much higher speed and would eliminate the subjective factor. The system can be used both in the pre-production stage, for sewing machines adjustment, and also in product inspection. The ability to recognize flaws and stop production immediately after the occurrence of the defect is important for clothing manufacturers.

The automatic control system may use different technologies for image acquisition, containing mechanical components, computer software, video cameras, lighting and video equipment. In particular, an automatic defect detection is based on an electro-optical device for fabric surface inspection using a two-dimensional scanner of the warp and weft directions, or on a complex of video camera and uniform illumination source connected to video acquisition system [2].

2. THE SEAM PUCKERING DEFECT: CAUSES AND REMEDIES

The seam puckering phenomenon is defined as a local defect of a clothing item in the form of large ridges of material beside the seam and is considered one of the most serious defects in garment manufacturing [3]. The complete elimination of this flaw during pressing operations is almost impossible, and therefore in practice, it is often to accept a lower grade as normal. Consequently, the objective assessment of seam puckering is essential, such that the final product will be acceptable to the client [4].

Seam pucker may also be described as a differential shrinkage that arises throughout the seam line and is caused by the instability of the seam. Usually, wrinkling appears due to improper selection of stitching parameters and material properties, leading to an inequality of fabrics lengths that are sewn together and affecting the appearance characteristics. In serious cases, puckering can appear as a wave coming from the seams. Since sewing operation is subjected to excessive tensions, it produces a stretching of sewing threads, leading to an extension over the whole surfaces of the fabrics.

Although sewing threads have usually a controlled elasticity, they are overstretched when large tensions are implied in process. After sewing, the threads tend to relax, trying to return to the original length. As the stitches shrink, wrinkles appear in the material and can not be detected immediately, but in a later stage. The threads used in sewn products must also have a good stability to washing and ironing, as differential shrinkage between sewing thread and fabrics may cause puckering.

Other fabrics characteristics which affect seam stability and puckering are fabric density and structure. By stitching, threads snap the fiber material into a new position, inserting into material structure and tending to change it. This phenomenon is more obvious when the fabric is made of fine, dense and low resistance to compression yarns. In the case of differences in fiber composition, fabrics structure, extensibility and stability, puckers may occur due to feeding failure. In order to avoid this situation, it is necessary to adjust the presser foot pressure to a minimum value. The feeding systems used in stitching control are: a positive or negative differential conveyor, consisting of two teeth elements in front and behind the needle with adjustable amplitude, and a simple oriented tooth feed.

In order to reduce puckering, sewing machine and stitching parameters are adjusted. In the case of the sewing machine, adjustments are made on the conveyor mechanism, tension control and needle selection. Regarding the processing parameters, the stitching step should be as small as possible, while the value of cutting and sewing angle must be correlated with yarn and fabric structure. Using a similar fabric fiber composition thread with thermo stability, low elongation and recovery, puckers can be decreased or avoided.

3. AN OBJECTIVE SEAM PUCKERING EVALUATION METHOD

Subjective evaluation methods have the disadvantage a higher assessment time, differences between appraisals, partiality towards certain colors or models, and training needs. In the attempt of objectification, two SP synthetic indicators may be used for seam pucker description: related to width and to the length [5]. The hypothesis assumes that following wrinkled defect occurrence, the thickness of two layers sewn assembly increases, while the length decreases, comparing to the initial length of unraveled material. In these conditions, the following formula can be used:
where $t_s$ = seam thickness, $t$ = fabric thickness, $l$ = length of unraveled fabric, $l_s$ = length of sewn assembly. However, incoherence and time-consuming are noticed for these assessments.

Image processing techniques have been already applied in the textile industry. Research was carried out to investigate the cross section of fibers, yarn structure, yarn thickness [6], texture fault detection, seam pucker etc. Image processing is sometimes combined with a classification/recognition step achieved using neural networks. A large review paper on this field, including many textile applications, has been published by [7].

The assessment of seams is one of the research topics in the aim of textile industry automation. The foundations of this field start with a geometric modeling of puckering and a review of the methods and techniques available at that time, in the view of measurement [8]. In [9], the use of a $k$ nearest neighbor classifier achieved an 81% rate of successful classification rate compared with human experts. This implementation is trying to improve a previous one from the same authors, presented in [10]. A wavelet based detectors of surface smoothness or wrinkles and puckering defects have been used by [11], joined with a 3D scanning system.

Our implementation was derived from [12] and involves a spectral image analysis using Fourier transform, and an unsupervised neural network, Kohonen Map to classify material specimens, which are the input images into five discrete degrees of quality, to grade 5 (best) to grade 1 (the worst). A similar approach was proposed using fractal theory [13]. The learning and testing stages are depicted in figure 1. The next paragraphs will present the basics of our processing scheme.

\[
SP = \frac{t_s - 2t}{2t} \times 100 \% \quad \text{or} \quad SP = \frac{l - l_s}{l_s} \times 100 \% \quad (1)
\]

\[
\sigma_n^2(t) = w_1(t)\sigma_1^2(t) + w_2(t)\sigma_2^2(t) \quad (2)
\]
Kohonen network can be described as follows [16]: all neurons that are in the neighborhood of the winning node. In summary, the basic rules of the neighborhood, as those nodes in a square centered on the winning node. The weights are updated for the same way, the DFT image can be retransformed in the spatial domain as an inverse transform:

\[
\text{Update the weights of the selected unit and its neighbors, thus increasing the level of matching,}
\]

The node with the best match wins the competition. This node is set as follows:

\[
\|X - W_c\| = \min\{\|X - W_i\|\}
\]

where \(c\) is the best node. After the winning node has been identified, the next step is to identify its neighborhood, as those nodes in a square centered on the winning node. The weights are updated for all neurons that are in the neighborhood of the winning node. In summary, the basic rules of the Kohonen network can be described as follows [16]:

- Locate the unit in the competitive layer whose weight fits best with the input,
- Update the weights of the selected unit and its neighbors, thus increasing the level of matching,
- Decrease the neighborhood size and adjust the weights during the iterations of the learning process

4. RESULTS

The input image is represented by a sewn sample image with puckering. At the beginning of the learning or testing framework, a preprocessing block was introduced, due to his main role in filtering. As in seam defects detection, color is not necessary; the acquired images are transformed to grayscale (figure 2 a).

![Grayscale image of a sewn presenting puckering, DFT amplitude b) and phase c) result](image)

Fig. 2: Grayscale image of a sewn presenting puckering, DFT amplitude b) and phase c) result

The result of a DFT is represented by the amplitude and phase of frequency components of the input image. The amplitude shows how much of a particular frequency is being presented in the image, while the phase represents how the signal is offset from the origin, or particularly, how much the sinus wave is shifted to the left or the right, as shown in figure 2 b) and c).

Fig. 3: The training set.

Our classification approach of puckering is based on series of samples that have been categorized according to some human experts. In this sense, the puckering features presented in the learning and test images have been pre-classified using the seam puckering quality standard. In the case of the proposed framework, the image features are extracted using spectral analysis by Fourier transform and the results stored in an array. We have down-sampled the corresponding array, in order to fit into the low resolution Kohonen Map, of a 100x100 size. The network training stage will consist in presenting five input vectors (derived from the down-sampled arrays), representing the puckering grades. The network learning stops when the error falls below a value that is very close to zero. The puckering classification consists in providing an input vector derived from the image supposed to be classified. A scalar product between the input values vectors and the weighted training images is computed. The result will be assigned to one of the five classes of which the input image belongs.

This method requires the image acquisition of samples in special conditions. An oblique light is applied on the material and, due to the wrinkled material appearance, the shadows will highlight the nonconformities of the fabric surface.
The investigation was performed on 26 samples of 100% polyester plain woven fabric, with 21 cm⁻¹ warp and weft density, and 170 grams/sqm specific weight. Specimens were cut into 10x10 cm sizes and midst sewn in pairs using 301 type lockstitch and a 4 cm⁻¹ seam density. Two colors of sewing thread were used: white to the needle and red to the bobbin, with 80 Nm sewing thread count, 100% PES.

The network was trained using the features images from figure 3, extracted using the DFT. In order to test the functionality of the network another set of 21 test images was used. These images were originally classified subjectively using visual information. The classification results using the Kohonen network are as follows:

- 71.42% of the images were classified correctly.
- 28.58% of the images were misclassified.

5. CONCLUSIONS

The applicability domain of the presented framework is in the textile industry, namely seams quality control and sewn assemblies classification in terms of visual quality. Various algorithms have been applied on the acquired images in order to improve their processability. Currently, defect detection is done using input images containing only horizontal seams. For further development of the application, fault detection will be completed on several types of stitches and seam shapes, for example, circular.

The image classification is done using visual information, based on subjective standard images. We have created five quality classes using puckering images, used in the training of the neural network. By processing a large number of samples, classification could be redefined and improved. The detection of seams defects will be further investigated using three images categories, containing horizontal seams from clothing manufacturing, airbag assembly and automotive upholstery.
